Abstract

We consider the problem of joint source-channel coding for transmitting K samples of a complex Gaussian source over $T = bK$ uses of a block-fading multiple input multiple output (MIMO) channel with M transmit and N receive antennas. We consider the case when we are allowed to code over L blocks. The channel gain is assumed to be constant over a block and channel gains for different blocks are assumed to be independent. The performance measure of interest is the rate of decay of the expected mean squared error with the signal-to-noise ratio (SNR), called the distortion SNR exponent. We first show that using a broadcast strategy as in [1], but with a different power and rate allocation policy, the optimal distortion SNR exponent can be achieved for bandwidth efficiencies $0 \leq b < (|N-M|+1)/\min(M,N)$. This is the first time the optimal exponent is characterized for $1/\min(M,N) < b < (|N-M|+1)/\min(M,N)$. Also, for $b > MNL^2$, we show that the broadcast scheme achieves the optimal exponent of MNL. Special cases of this result have been derived in [1] for the $L = 1$ case and in [2] for $M = N = 1$. We then propose a digital layered transmission scheme that uses both time layering and superposition. This includes many known schemes in [1, 3] as special cases. The proposed scheme is at least as good as the currently best known schemes for the entire range of bandwidth efficiencies, whereas at least for some M, N, and b, it is strictly better than the currently best known schemes.

I. Introduction

A. Problem Statement

Consider the problem of transmitting K samples of a complex Gaussian source in $T = bK$ uses of an $M \times N$ MIMO channel with block fading where b is the ratio of the channel bandwidth to the source bandwidth. The channel is given by

$$\mathbf{y}_t = \sqrt{\frac{\rho}{M}}\mathbf{H}_{\lceil \frac{Lt}{T} \rceil}\mathbf{x}_t + \mathbf{w}_t, \quad t = 1, \ldots, T \tag{1}$$

where: T is the duration (in channel uses) of the transmitted block; $\mathbf{H}_l \in \mathbb{C}^{N \times M}$, $l = 1, \ldots, L$, is the channel matrix for $\frac{(l-1)T}{L} < t \leq \frac{lT}{L}$ containing random i.i.d. elements $h_{i,j}^l \sim \mathcal{CN}(0,1)$ (Rayleigh independent fading). The channel matrix for different blocks are independent; $\mathbf{x}_t$ is the transmitted signal at time t; the transmitted codeword, $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_T]$, is normalized such that $\text{tr}(\mathbb{E}[\mathbf{X}^{\mathsf{H}}\mathbf{X}]) \leq MT$; $\mathbf{w}_t \sim \mathcal{CN}(0, I^{M \times M})$ is additive white Gaussian noise; ρ denotes the Signal-to-Noise Ratio (SNR), defined as the ratio of the average received signal energy per receiving antenna to the noise per-component variance. We also define $m = \min\{M, N\}$ and $n = \max\{M, N\}$.

When the channel state information is available at both the transmitter and the receiver, Shannon's separation theorem applies and separate source and channel coding is optimal. However, when the channel state information is available only at the receiver, the separation theorem fails and the optimal scheme requires joint source and channel coding.

Consider a family of joint source-channel coding schemes $\{\mathcal{SC}_b(\rho)\}$ of spectral efficiency $1/b$, where $\mathcal{SC}_b(\rho)$ denotes the scheme that operates at SNR ρ. Corresponding to the coding scheme $\mathcal{SC}_b(\rho)$, let $D(\rho)$ denote the distortion averaged over the source, the noise, and the channel realization. The *distortion SNR exponent* of the family is defined as the limit

$$a(b) = -\lim_{\rho\to\infty} \frac{\log D(\rho)}{\log \rho}. \tag{2}$$

The distortion SNR exponent *of the channel*, denoted by $a^\star(b)$, is the supremum of $a(b)$ over all possible coding families. We are interested in characterizing $a^\star(b)$ for the block fading MIMO channel.

B. Prior Work

The diversity multiplexing tradeoff [4] is closely related to the problem considered here. In [4], Zheng and Tse consider the problem of transmitting digital information over a MIMO fading channel. For a family of coding schemes $C_r(\rho)$ whose rate grows as $r \log \rho$, where r is referred to as the multiplexing rate, the diversity order of the family is defined as the limit

$$d(r) = -\lim_{\rho\to\infty} \frac{\log P_e(\rho)}{\log \rho} \tag{3}$$

where $P_e(\rho)$ denotes the probability of decoding error corresponding to the coding scheme $C(\rho)$. The diversity order of the channel, $d^*(r)$, is the supremum of $d(r)$ taken over all possible coding families. In [4], for the Rayleigh fading channel, the diversity order was determined to be

$$d^*(r) = (M-k)(N-k) - (M+N-1-2k)(r-k) \tag{4}$$

where $k = \lfloor r \rfloor$ for $0 < r < m$ and 0 for $r > m$.

The distortion SNR exponent problem has been considered previously by many researchers in [1–3, 5–13]. Distortion SNR exponent was first defined by Laneman *et al.* in [11]. In [11–13] the authors compared the performance of two schemes for parallel fading channels (a) a separation based scheme and (b) a multiple description based scheme where the message sent on each channel corresponded to a description. If the multiplexing rate of the channel code is low the probability of outage is low. However, the corresponding quantization error is large. When the multiplexing rate is increased quantization error decreases but outage probability increases. For these schemes, the optimal multiplexing rate is chosen such that it maximizes the distortion SNR exponent. Goldsmith and Holliday [9, 10] consider a separation based scheme for the MIMO channel and derive the optimal operating point (multiplexing rate of the channel code) that maximizes the distortion SNR exponent.

An upper bound on $a^\star(b)$ was derived by Caire and Narayanan [5–7] and by Gunduz and Erkip [1–3, 8] by assuming that the transmitter is informed of the channel realization $\mathbf{H} = \{\mathbf{H}_1, \ldots, \mathbf{H}_L\}$. In this

case, Shannon's separation theorem applies and the optimal distortion is given by $D(\mathbf{H}) = 2^{-2R(\mathbf{H})}$ where $R(\mathbf{H}) = \frac{1}{L}\sum_l \log\det(I + \frac{\rho}{M}\mathbf{H}_l\mathbf{H}_l^H)$. The distortion SNR exponent is then the exponent corresponding to $E_{\mathbf{H}}[D(\mathbf{H})]$. This has been computed in closed form for the Rayleigh fading channel in [1–3, 5–8] and is given by

$$a_{IT}(b) = \sum_{i=1}^{m} \min(b, (2i - 1 + n - m)L). \tag{5}$$

Note that this is an upper bound and is not known to be achievable.

The schemes by Laneman *et al.* [11–13] and Goldsmith and Holliday [9, 10] are far away from the informed transmitter upper bound. In [5–7], two hybrid digital analog (HDA) scheme were proposed for $b < 1/m$ and $b > 1/m$. For $b < 1/m$, in the HDA scheme, the transmitted signal was chosen to be a superposition of an analog layer with a digital layer. The analog layer is formed by a fraction mb of the source symbols. The remaining source symbols were quantized and transmitted in the digital layer. The scheme was shown to achieve the upper bound for $b < 1/m$. For $b > 1/m$, the HDA scheme involved transmitting in two "time" layers (i.e., two layers multiplexed in time). A digital layer of bandwidth $b - 1/m$ ($T - K/m$ channel uses) was used to transmit the quantized source and the quantization error was transmitted in an analog layer of bandwidth $1/m$. This scheme improved on the exponent obtained by the separation based scheme. However, the gap to the upper bound was still large.

In [1, 3, 8], Gunduz and Erkip proposed a hybrid layering scheme (HLS) that improved on the exponent obtained by the HDA scheme for $b > 1/m$ by allowing for multiple digital time layers instead of the single digital layer of the HDA scheme. They also proposed a broadcast scheme (BS) that involved transmitting a superposition of several digital layers. For the $L = 1$ case, the broadcast scheme was shown to achieve an exponent of MN for $b > MN$ which overlaps with the upper bound and is hence optimal. In this case, for the region $1/m < b < MN$, a characterization of the best achievable distortion SNR exponent is not available. Currently the best known exponents are obtained by the hybrid layering scheme and broadcast strategy of Gunduz and Erkip [1]. In [2], Gunduz and Erkip considered the broadcast scheme for parallel channels which corresponds to $M = N = 1$ and $L > 1$ in our model and they showed that the broadcast scheme achieves an exponent of MNL for $b > L^2$ and is hence optimal. Note that throughout this paper we refer to a superposition coding scheme as a broadcast scheme.

In other related work, Dunn and Laneman [14] consider the distortion to be of the form

$$D \approx C(b)\log(b\rho)^p \rho^{-a(b)} \tag{6}$$

and compare several schemes using this approximation.

C. Main Results

The main results presented in this paper are summarized below.

1) We fully characterize the exponent achievable by any broadcast (superposition) scheme. An achievable exponent and the corresponding rate and power allocation are specified in Theorem 2.1. In Theorems 2.2 and 2.3, we show that no broadcast scheme can outperform the scheme in Theorem 2.1.

2) We show that the broadcast scheme in [1] when used with a different power and rate allocation than that specified in [1] achieves the optimal exponent mb for $b < \frac{n-m+1}{m}$.
3) The broadcast scheme with the proposed power and rate allocation policy achieves the optimal exponent of MNL for $b > MNL^2$. Special cases of this result have been derived in [1] for the $L = 1$ case and in [2] for $M = N = 1$.
4) The proposed power and rate allocation policy for the broadcast scheme becomes identical to that specified in [1] for $MNL - (M + N - 1)L < b < MNL - (M + N - 1)(L - 1)$. For other $b < MNL^2$ the distortion SNR exponent obtained is larger than the broadcast scheme exponent of [1].
5) We propose a time layering scheme in which the last time layer is a broadcast layer, i.e, the last time layer is a superposition of several layers. The distortion SNR exponent obtained using this scheme is shown to be better than the exponent obtained using the HLS scheme of [1]. We refer to this scheme as LSBLEND as an abbreviation for Layered Scheme with a Broadcast Layer at the end.
6) We also propose a layering strategy, termed the Box scheme, which generalizes BS and LSBLEND proposed in this paper and the strategies considered earlier in [1, 5] by allowing for superposition and time layers simultaneously. All previously known schemes are special cases of the Box scheme and hence the Box scheme performs at least as well as these schemes. However, the optimal distortion SNR exponent for the Box scheme is difficult to obtain. We present a suboptimal algorithm to compute an achievable distortion SNR exponent. The scheme with the suboptimal algorithm is shown to outperform all previously known schemes, including BS and LSBLEND which are proposed in this paper, for some range of b, whereas, for the considered examples, they are at least as good as previously known schemes for all b.

Some of these results have been reported in a conference version of this paper [15].

D. Organization of the paper

The paper is organized as follows. The proposed schemes - Broadcast Scheme, LSBLEND, and Box Scheme, for the $L = 1$ case, are discussed in section II-A, II-B, and II-C respectively. The results for $L > 1$ case are presented in section III. In section IV, we present some examples that demonstrate that the proposed schemes achieve better distortion SNR exponent than previously known schemes and finally we conclude in section V.

II. Proposed Schemes

In this section we present the proposed schemes for the L=1 case. The results for the $L > 1$ case are presented in section III.

A. Digital Layering using Superposition Only

Consider the broadcast scheme shown in Fig. 1. The scheme has N_s superposition layers with the ith superposition layer being assigned a power level of $\rho^{\gamma_{i-1}} - \rho^{\gamma_i}$ where ρ is the signal-to-noise ratio and

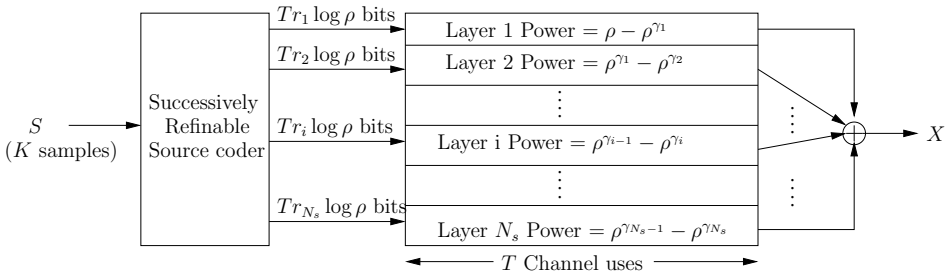

Fig. 1. Broadcast Schemes

$\gamma_i \geq 0$ is a decreasing sequence with $\gamma_0 = 1$. The source is compressed into N_s layers such that it is successively refinable. The rate in the ith refinement layer is $\frac{Tr_i \log \rho}{K} = br_i \log \rho$. Therefore, if a receiver estimates the source using the first J layers the resulting distortion would be $2^{-\sum_{i=1}^{J} br_i \log \rho} = \rho^{-b\sum_{i=1}^{J} r_i}$. The ith refinement layer is transmitted in the ith superposition layer. Since $Tr_i \log \rho$ bits have to be transmitted in T uses of the channel, the resulting rate of transmission in the ith broadcast layer is $r_i \log \rho$. For mathematical convenience in deriving the expressions, we will assume that in the last layer (layer $N_s + 1$) the remaining power of $\rho^{\gamma_{N_s}}$ is used to transmit Gaussian noise. Therefore, $\gamma_{N_s+1} = 0$ and $r_{N_s+1} = 0$. The channel codes used in the broadcast layers are assumed to achieve the diversity multiplexing tradeoff [4] corresponding to that layer. Here achieving the diversity multiplexing tradeoff refers to achieving an error probability that decays as $\rho^{-d(r)}$ with a coding rate that grows as $r \log \rho$, where $d(r)$ is the optimal diversity multiplexing tradeoff function corresponding to that layer.

At the receiver, the decoder attempts to decode as many layers as it can using successive interference cancellation starting from the first layer. That is, it decodes layer 1 by treating the signal transmitted in layers 2 to N_s as noise. On successful decoding it removes the contribution of layer 1 from the received signal and repeats the process for layer 2 and so on. It then makes an estimate of the source using all the layers it is able to decode.

To compute the distortion SNR exponent of the broadcast scheme, we first characterize the diversity multiplexing tradeoff of the broadcast scheme in the following lemma.

Lemma 2.1: If the multiplexing gain in the ith layer of the broadcast scheme is $r_i = k(\gamma_{i-1} - \gamma_i) + \delta$ where $k \in \{0, 1, \ldots, m-1\}$ and $0 \leq \delta < \gamma_{i-1} - \gamma_i$, $\gamma_{i-1} > \gamma_i \geq 0$, then, the achievable diversity in the ith layer of the broadcast scheme, assuming that the message transmitted in the previous layers is available at the receiver, is given by

$$d^\star(r_i, \gamma_{i-1}, \gamma_i) = (m-k)(n-k)\gamma_{i-1} - (m+n-1-2k)\delta. \tag{7}$$

That is, if

$$X = \frac{1}{\sqrt{\rho}} \left(\sum_{i=1}^{N_s} \sqrt{(\rho^{\gamma_{i-1}} - \rho^{\gamma_i})} X_i + \sqrt{\rho^{\gamma_{N_s}}} N_1 \right), \tag{8}$$

where $X_i, N_1 \sim \mathcal{CN}(0, I^{M \times M})$, is transmitted over a MIMO channel $Y = \sqrt{\frac{\rho}{M}} \mathbf{H} X + N$, then the probability of the outage event

$$\mathcal{A}_i = \{H : I(X_i; Y | \mathbf{H} = H, X_1, \ldots X_{i-1}) < r_i \log \rho\} \tag{9}$$

is given by $P(\mathcal{A}_i) \doteq \rho^{-d^\star(r_i,\gamma_{i-1},\gamma_i)}$. (Here $A \doteq B$ is used to denote that A and B are equal in exponential order, i.e., $\lim_{\rho\to\infty} \frac{\log A}{\log \rho} = \lim_{\rho\to\infty} \frac{\log B}{\log \rho}$.) Note that the term $\sqrt{\rho^{\gamma_{N_s}}}N_1$ in X is the Gaussian noise transmitted in layer N_s+1 and is introduced for mathematical convenience. It should not be confused with noise from the channel.

Proof:

$$P(\mathcal{A}_i) = P\left(\log \frac{\det(I + \frac{1}{M}\rho^{\gamma_{i-1}}\mathbf{H}\mathbf{H}^H)}{\det(I + \frac{1}{M}\rho^{\gamma_i}\mathbf{H}\mathbf{H}^H)} < r_i \log \rho\right). \tag{10}$$

Let $\lambda_1, \ldots, \lambda_m$ denote the non-zero ordered eigenvalues of $\mathbf{H}\mathbf{H}^H$ with $\lambda_1 \leq \lambda_2 \leq \ldots \lambda_m$. As in [4], let $\alpha_j = -\frac{\log \lambda_j}{\log \rho}$. Therefore, $\alpha_1 \geq \alpha_2 \geq \ldots \alpha_m$. Then

$$P(\mathcal{A}_i) = P\left(\log \prod_{j=1}^{m} \frac{1 + \frac{1}{M}\rho^{\gamma_{i-1}-\alpha_j}}{1 + \frac{1}{M}\rho^{\gamma_i-\alpha_j}} < r_i \log \rho\right). \tag{11}$$

At high SNR, we obtain $P(\mathcal{A}_i) \doteq P(\mathcal{A}')$ where

$$\mathcal{A}' = \left\{\alpha : \sum_{j=1}^{m}(\gamma_{i-1} - \alpha_j)^+ - \sum_{j=1}^{m}(\gamma_i - \alpha_j)^+ < r_i\right\}. \tag{12}$$

Starting from Lemma 3 of [4] and following in the footsteps of [4] we obtain

$$P(\mathcal{A}') = \int_{\mathcal{A}'} p(\alpha)d\alpha \doteq \int_{\mathcal{A}'\cap\boldsymbol{\alpha}^+} \prod_{j=1}^{m} \rho^{(2j-1+n-m)\alpha_j} d\alpha \tag{13}$$

for the Rayleigh fading channel. Therefore the outage probability is given by $P(\mathcal{A}_i) \doteq \rho^{-d^\star(r_i,\gamma_{i-1},\gamma_i)}$ where

$$d^\star(r_i, \gamma_{i-1}, \gamma_i) = \inf_{\mathcal{A}'\cap\boldsymbol{\alpha}^+} \sum_{j=1}^{m}(2j - 1 + n - m)\alpha_j. \tag{14}$$

For $r_i = k(\gamma_{i-1} - \gamma_i) + \delta$ where $k \in [0, 1, \ldots, m-1]$ and $0 \leq \delta < \gamma_{i-1} - \gamma_i$, the infimum in (14) occurs when $\alpha = \alpha^*$ where

$$\alpha_j^* = \begin{cases} \gamma_{i-1}, & 1 \leq j < m-k; \\ \gamma_{i-1} - \delta, & j = m-k; \\ 0, & m-k < j \leq m. \end{cases} \tag{15}$$

Substituting α^* in (14) we obtain

$$\begin{aligned} d^\star(r_i, \gamma_{i-1}, \gamma_i) &= \left(\sum_{j=1}^{m-k-1}(2j - 1 + n - m)\right)\gamma_{i-1} + (2(m-k) - 1 + n - m)(\gamma_{i-1} - \delta) \\ &= \left(\sum_{j=1}^{m-k}(2j - 1 + n - m)\right)\gamma_{i-1} - (2(m-k) - 1 + n - m)\delta \\ &= (m-k)(2\frac{m-k+1}{2} - 1 + n - m)\gamma_{i-1} - (m + n - 1 - 2k)\delta. \end{aligned}$$

This then gives the desired result. ■

Note that the probability of the outage event $\mathcal{A}_i$ discussed in lemma 2.1 is different from (a) the outage probability of layer i and (b) the outage probability of layer i given layers 1 to $i-1$ are decoded. Rather,

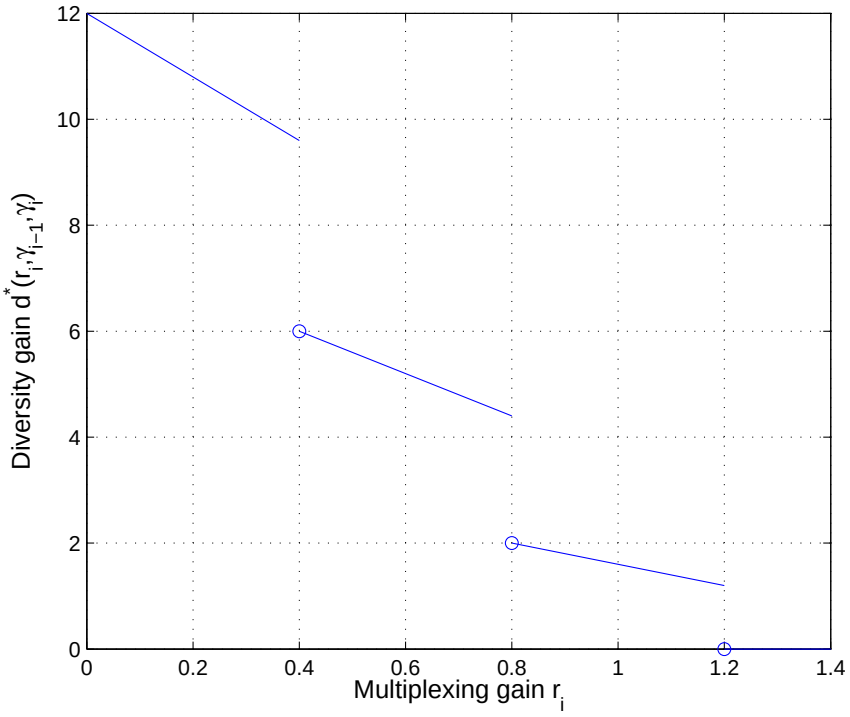

Fig. 2. Diversity Multiplexing tradeoff corresponding to a broadcast layer with $\gamma_{i-1} = 1$ and $\gamma_i = 0.6$ for a 3×4 MIMO system

it is the probability of outage of layer i with a genie aided decoder where the genie provides the signal that is transmitted in layers 1 to $i-1$.

We will refer to the rate of decay of $P(\mathcal{A}_i)$ with ρ, i.e., $\lim_{\rho\to\infty} \frac{\log P(\mathcal{A}_i)}{\log \rho} = d^*(r_i, \gamma_{i-1}, \gamma_i)$, as the diversity of layer i. In Fig. 2, as an example, the diversity multiplexing tradeoff corresponding to a superposition layer in the broadcast scheme is plotted. Note that it is discontinuous.

Note that the diversity multiplexing tradeoff of Zheng and Tse [4] specified in (4) corresponds to the case when $\gamma_{i-1} = 1$ and $\gamma_i = 0$. From Lemma 2.1 and (4) we can verify that $d^*(r_i, 1, 0) = d^*(r_i)$. To keep the notation brief, in such cases, we will use $d^*(r_i)$ in place of $d^*(r_i, 1, 0)$.

The broadcast scheme considered in [1] used $r_i = \gamma_{i-1} - \gamma_i$ and optimized the power allocation, γ_i's, in order to maximize the distortion SNR exponent. With this rate and power allocation, the resulting scheme had a distortion SNR exponent equal to $\min(b, MN)$. We show that by using a different rate and power allocation than that specified in [1], we can obtain the optimal exponent of mb for any $b < \frac{n-m+1}{m}$. Notice that in this region the broadcast scheme with the rate and power allocation specified in [1] performs quite poorly. Our main result in this section is the following theorem.

Theorem 2.1: The broadcast scheme achieves a distortion SNR exponent of $(k+1)b$, $k \in \{0, 1, \ldots, m-1\}$ for $\frac{(M-k-1)(N-k-1)}{k+1} < b < \frac{(M-k)(N-k)}{k+1}$ with power and rate allocation

$$\gamma_i = \left(\frac{b(k+1) - (M-k-1)(N-k-1)}{(M-k)(N-k) - (M-k-1)(N-k-1)} \right)^i \tag{16}$$

and

$$r_i = (k+1)(\gamma_{i-1} - \gamma_i) - \epsilon \tag{17}$$

for arbitrarily small $\epsilon > 0$.

Proof: The distortion is given by

$$D = \sum_{i=1}^{N_s} P(\text{Layer 1 to } i-1 \text{ decoded, layer } i \text{ decoding failed}) D_i + P(\text{All layers decoded}) D_{N_s+1} \tag{18}$$

where D_i is the distortion when only the first $i-1$ layers are used for reconstructing the source. If the layers $1, \ldots, i-1$ can be decoded, a source coding rate of $b\sum_{j=1}^{i-1} r_j$ can be obtained. Therefore $D_i = \rho^{-b\sum_{j=1}^{i-1} r_j}$.

We have

$$\begin{aligned} &P(\text{Layer } 1, \ldots, i-1 \text{ decoded, layer } i \text{ decoding failed}) \\ &= P(\text{Layer } 1, \ldots, i-1 \text{ decoded, layer } i \text{ decoding failed} \mid X_1, \ldots, X_{i-1} \text{ available to decode layer } i) \\ &\leq P(\text{Layer } i \text{ decoding failed} \mid X_1, \ldots, X_{i-1} \text{ available to decode layer } i) \\ &\doteq \rho^{-d^\star(r_i, \gamma_{i-1}, \gamma_i)}. \end{aligned} \tag{19}$$

If $d^\star(r_i, \gamma_{i-1}, \gamma_i) > 0$ for all i, then,

$$P(\text{All layers decoded}) = 1 - \sum_i P(\text{Layer } 1, \ldots, i-1 \text{ decoded, layer } i \text{ decoding failed} \doteq \rho^0. \tag{20}$$

From (18), (19), and (20) we have

$$D \doteq \sum_{i=1}^{N_s} \rho^{-(b\sum_{j=1}^{i-1} r_j + d^*(r_i, \gamma_{i-1}, \gamma_i))} + \rho^{-b\sum_{i=1}^{N_s} r_i}. \tag{21}$$

Let

$$a(i) = b\sum_{j=1}^{i-1} r_j + d^*(r_i, \gamma_{i-1}, \gamma_i) \tag{22}$$

be the exponent corresponding to the case when the ith layer is in outage and $a(N_s+1) = b\sum_{i=1}^{N_s} r_i$ the exponent when all layers are decoded. From (21), the distortion SNR exponent for the broadcast scheme is

$$a_{BS}(b) = \max_{r,\gamma} \min_i a(i). \tag{23}$$

In the following proof, we fix $r_i = (k+1)(\gamma_{i-1} - \gamma_i) - \epsilon$ and optimize the power allocation γ_i's for $i = 1$ to N_s in order to maximize the exponent. Note that $\gamma_0 = 1$.

In section A of the Appendix, using the Karush-Kuhn-Tucker (KKT) conditions, it is proved that for $b > \frac{(M-k-1)(N-k-1)}{k+1}$ the optimal exponent is obtained when all the exponents $a(i)$ are equal provided that the resulting solution satisfies $\gamma_i > \gamma_{i+1}$ for all i and $\gamma_{N_s} > 0$.

In order for $a(i) = a(i+1)$, from (22) we have

$$d^*(r_i, \gamma_{i-1}, \gamma_i) = br_i + d^*(r_{i+1}, \gamma_i, \gamma_{i+1}). \tag{24}$$

Since r_i is chosen to be $(k+1)(\gamma_{i-1}-\gamma_i)-\epsilon$, from (7) we have

$$d^*(r_i,\gamma_{i-1},\gamma_i)=(M-k)(N-k)\gamma_{i-1}-(M+N-1-2k)(\gamma_{i-1}-\gamma_i-\epsilon). \tag{25}$$

Substituting from (25) in (24) and using $r_i=(k+1)(\gamma_{i-1}-\gamma_i)$ we have

$$\begin{aligned}&(M-k)(N-k)\gamma_{i-1}-(M+N-1-2k)(\gamma_{i-1}-\gamma_i)\\&\quad=b(k+1)(\gamma_{i-1}-\gamma_i)+(M-k)(N-k)\gamma_i-(M+N-1-2k)(\gamma_i-\gamma_{i+1})+O(\epsilon).\end{aligned}$$

On simplifying we obtain

$$(\gamma_i-\gamma_{i+1})=\alpha(\gamma_{i-1}-\gamma_i)+O(\epsilon) \tag{26}$$

where

$$\alpha=\frac{b(k+1)-(M-k-1)(N-k-1)}{M+N-1-2k}. \tag{27}$$

We can use (26) recursively to obtain

$$\gamma_i-\gamma_{i+1}=\alpha^i(\gamma_0-\gamma_1)+O(\epsilon)=\alpha^i(1-\gamma_1)+O(\epsilon). \tag{28}$$

Therefore,

$$1-\gamma_i \;=\; \sum_{j=1}^{i}(\gamma_{j-1}-\gamma_j)=\sum_{j=1}^{i}\alpha^{j-1}(1-\gamma_1)+O(\epsilon)=\frac{1-\alpha^i}{1-\alpha}(1-\gamma_1)+O(\epsilon). \tag{29}$$

Furthermore, if $b\sum_{j=1}^{N_s}r_j=a(1)$, we have

$$\begin{aligned}b\sum_{j=1}^{N_s}(k+1)(\gamma_{j-1}-\gamma_j) &= (M-k)(N-k)-(M+N-1-2k)(1-\gamma_1)+O(\epsilon)\\ \Rightarrow b(k+1)\frac{1-\alpha^{N_s}}{1-\alpha}(1-\gamma_1) &= (M-k)(N-k)-(M+N-1-2k)(1-\gamma_1)+O(\epsilon)\\ \Rightarrow(1-\gamma_1) &= \frac{(M-k)(N-k)(1-\alpha)}{b(k+1)(1-\alpha^{N_s})+(M+N-1-2k)(1-\alpha)}.\end{aligned}$$

From (27) we have

$$(1-\gamma_1)=\frac{(M-k)(N-k)(1-\alpha)}{(M-k)(N-k)-b(k+1)\alpha^{N_s}}. \tag{30}$$

From (29)

$$(1-\gamma_i) \;=\; \frac{(M-k)(N-k)(1-\alpha^i)}{(M-k)(N-k)-b(k+1)\alpha^{N_s}} \tag{31}$$

$$\gamma_i \;=\; \frac{(M-k)(N-k)\alpha^i-b(k+1)\alpha^{N_s}}{(M-k)(N-k)-b(k+1)\alpha^{N_s}}. \tag{32}$$

Consider the case when $0\le\alpha\le 1$, i.e., when $\frac{(M-k-1)(N-k-1)}{k+1}\le b\le\frac{(M-k)(N-k)}{k+1}$. Since $1\ge\alpha^i$ and since $(M-k)(N-k)/(b(k+1))>1>\alpha^{N_s}$, from (31) it follows that $\gamma_i\le 1$. From (32), since $(M-k)(N-k)/(b(k+1))>1>\alpha^{N_s-i}$, we have $\gamma_i\ge 0$ and we also observe that γ_i is a decreasing sequence in i. Therefore, this a valid power allocation.

The resulting exponent is $b(k+1)\frac{(M-k)(N-k)(1-\alpha^{N_s})}{(M-k)(N-k)-b(k+1)\alpha^{N_s}}$ and on taking the limit as $N_s\to\infty$ we obtain $b(k+1)$. ■

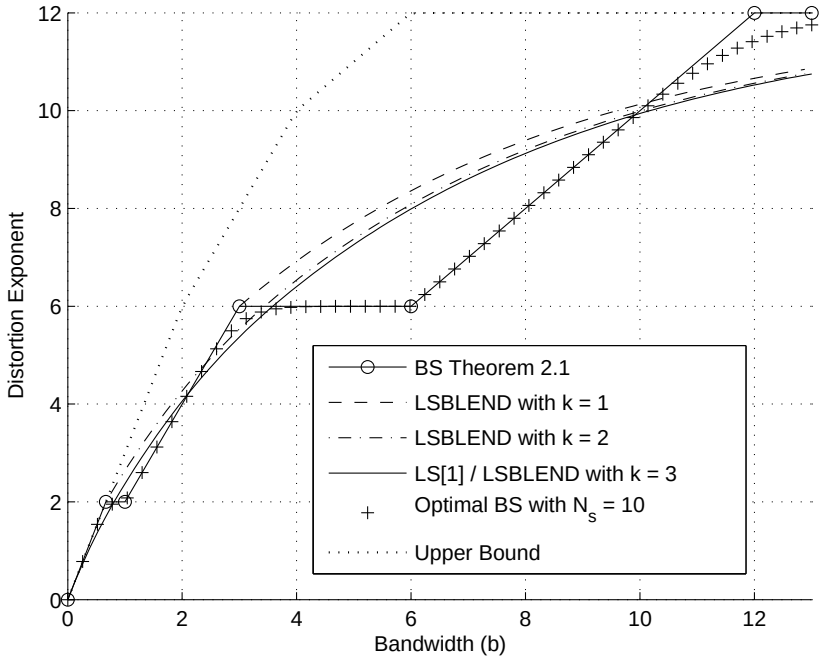

Fig. 3. Distortion SNR exponent for $M = 3, N = 4$

For the region $\frac{(M-k)(N-k)}{k+1} \leq b \leq \frac{(M-k)(N-k)}{k}$, Theorem 2.1 does not specify any achievable exponent. But notice that the exponent corresponding to both $b = \frac{(M-k)(N-k)}{k+1}$ and $b = \frac{(M-k)(N-k)}{k}$ is $(M-k)(N-k)$. For this region, we can ignore the additional bandwidth $b - \frac{(M-k)(N-k)}{k+1}$ and use a power allocation corresponding to $b = \frac{(M-k)(N-k)}{k}$ to achieve an exponent of $(M-k)(N-k)$. The resulting achievable distortion SNR exponent curve is continuous and is flat in the region $\frac{(M-k)(N-k)}{k+1} \leq b \leq \frac{(M-k)(N-k)}{k}$ for $k = 1$ to $m-1$. and for $b > MN$.

Corollary 2.1: The optimal distortion SNR exponent for $b < (n-m+1)/m$ is mb.

Proof: The result is obtained by comparing the upper bound in (5) with the achievable exponent specified in Theorem 2.1 for the case when $k = (m-1)$. ■

For $b < (n-m+1)/m$ and $b > mn$, BS achieves the optimal exponent (it matches the informed transmitter upper bound) and hence the power and rate allocation specified in Theorem 2.1 is optimal. For the region between these two values, the next two results prove that the exponent achieved in Theorem 2.1 is the optimal exponent achievable by any superposition (broadcast) scheme. This is shown by finding an upper bound to the exponent of any superposition scheme, for any power allocation and number of layers, that matches the achievable exponent of Theorem 2.1. This also calls for schemes that are not based on superposition alone in order to improve on the achievable exponent in this region (discussed in the next sections).

Theorem 2.2: For $b \leq \frac{(M-k)(N-k)}{k}$, the distortion SNR exponent of the broadcast scheme $a_{BS}(b) \leq (M-k)(N-k)$.

Proof: Recall that the exponent of the broadcast scheme is given by $a_{BS}(b) = \min_i a(i)$ where $a(i)$

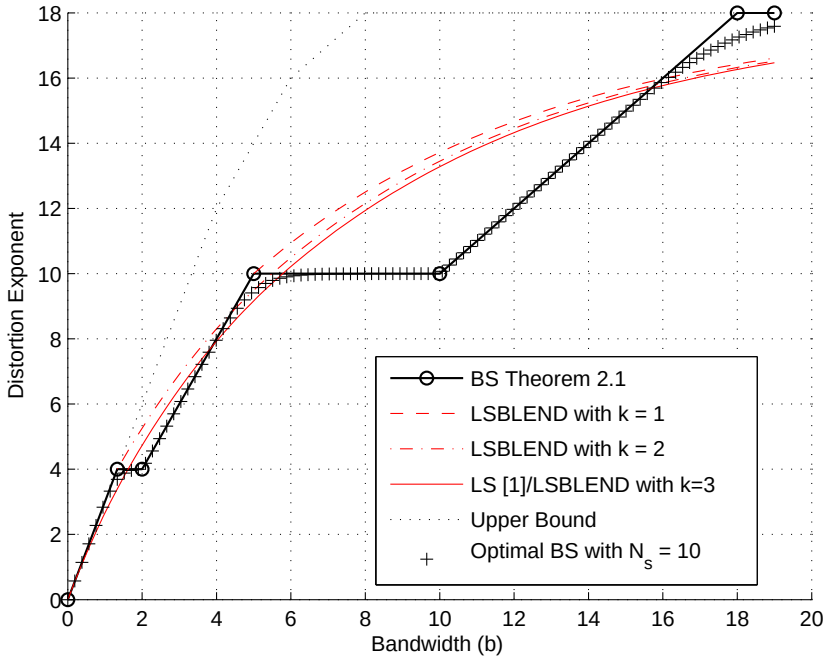

Fig. 4. Distortion SNR exponent for $M = 3, N = 6$

is as specified in (22).

Let us fix b and k such that $(M-k)(N-k)/k \geq b$. Let us assume that there exists a power and rate allocation such that the exponent $a_{BS}(b) > (M-k)(N-k)$, then since $a_{BS}(b) = \min_i a(i)$, then for all i from 1 to $N_s + 1$ we must have $a(i) > (M-k)(N-k)$. As before, without loss of generality, let the rate used in the ith layer be $r_i = k_i(\gamma_{i-1} - \gamma_i) + \delta_i$, for some integer k_i and $0 \leq \delta_i < \gamma_{i-1} - \gamma_i$. We will now show that if $a_{BS}(b) > (M-k)(N-k)$ were to be true, then $k_i < k$ for all i.

The gist of the proof is as follows. If, to the contrary, $k_i \geq k$ for some i, then there must be a smallest value of i (say i^*) for which this is true. That is, there must be an $i^* \geq 1$, for which $k_{i^*} \geq k$ and $k_i \leq k-1$ for all $i = 1$ to $i^* - 1$. We will now show that $a(i^*)$ cannot be larger than $(M-k)(N-k)$.

We have

$$a(i^*) = b \sum_{i=1}^{i^*-1} r_i + d^*(r_{i^*}, \gamma_{i^*-1}, \gamma_{i^*}) \tag{33}$$

Since, $r_i = k_i(\gamma_{i-1} - \gamma_i) + \delta_i$, clearly $r_i \leq (k_i + 1)(\gamma_{i-1} - \gamma_i)$. Therefore,

$$\begin{aligned}
a(i^*) &\leq b\sum_{i=1}^{i^*-1}(k_i+1)(\gamma_{i-1}-\gamma_i) + d^*(r_{i^*}, \gamma_{i^*-1}, \gamma_{i^*}) \\
&\leq b\sum_{i=1}^{i^*-1}(k)(\gamma_{i-1}-\gamma_i) + d^*(r_{i^*}, \gamma_{i^*-1}, \gamma_{i^*}) \quad (\because k_i \leq k-1, \text{ for } \ i < i^*) \\
&= bk(1-\gamma_{i^*-1}) + d^*(r_{i^*}, \gamma_{i^*-1}, \gamma_{i^*}) \\
&\leq (M-k)(N-k)(1-\gamma_{i^*-1}) + d^*(r_{i^*}, \gamma_{i^*-1}, \gamma_{i^*}) \quad (\because b \leq (M-k)(N-k)/k) \\
&\leq (M-k)(N-k)(1-\gamma_{i^*-1}) + (M-k_{i^*})(N-k_{i^*})\gamma_{i^*-1} \quad (\because \delta_{i^*} \geq 0) \\
&\leq (M-k)(N-k)(1-\gamma_{i^*-1}) + (M-k)(N-k)\gamma_{i^*-1} \quad (\because k_{i^*} \geq k) \\
&= (M-k)(N-k).
\end{aligned}$$

For $a_{BS} > (M-k)(N-k)$, we require $a(i) > (M-k)(N-k), \forall i$ and, hence, we must have that $k_i \leq k-1$, for all $i = 1, \ldots, N_s$. This implies that $r_i \leq k(\gamma_{i-1} - \gamma_i)$. But, in this case,

$$a(N_s+1) = b\sum_{i=1}^{N_s} r_i \leq bk(1-\gamma_{N_s}) \leq (M-k)(N-k).$$

Therefore, our assumption that $a_{BS}(b)$ can be greater than $(M-k)(N-k)$ for $b < (M-k)(N-k)/k$ is not valid. Hence proved. ■

As pointed out in the discussion after Theorem 2.1, the achievable exponent for $(M-k)(N-k)/(k+1) \leq b \leq (M-k)(N-k)/k$ is $(M-k)(N-k)$. This combined with the upper bound specified in Theorem 2.2 proves that this is the best achievable exponent using any broadcast scheme for this range of b.

Theorem 2.3: For $b > (M-k-1)(N-k-1)/(k+1)$ the distortion SNR exponent of the broadcast scheme $a_{BS}(b) \leq b(k+1)$.

Proof: Recall that the exponent of the broadcast scheme is given by $a_{BS}(b) = \min_i a(i)$ where $a(i)$ is as specified in (22). The idea of the proof is similar to that in the proof of the previous theorem. Again we fix b and k such that $b > (M-k-1)(N-k-1)/(k+1)$. Let us assume that there exists a power and rate allocation policy such that $a_{BS}(b) > b(k+1)$. Let the rate allocation be $r_i = k_i(\gamma_{i-1} - \gamma_i) + \delta_i$ as before.

The proof is similar to that of the previous theorem and is to first show that $k_i \leq k$ for all i. As before, let $i^* \geq 1$ be such that Let $k_i \leq k$ for $i = 1$ to $i^* - 1$ and $k_{i^*} \geq k+1$. We have

$$\begin{aligned}
a(i^*) &= b\sum_{i=1}^{i^*-1} r_i + d^*(r_{i^*}, \gamma_{i^*-1}, \gamma_{i^*}) \\
&\leq b(k+1)(1-\gamma_{i^*-1}) + (M-k_{i^*})(N-k_{i^*})\gamma_{i^*-1} \\
&\qquad (\because r_i \leq (k_i+1)(\gamma_{i-1}-\gamma_i) \leq (k+1)(\gamma_{i-1}-\gamma_i) \text{ for } i < i^*) \\
&\leq b(k+1)(1-\gamma_{i^*-1}) + (M-k-1)(N-k-1)\gamma_{i^*-1} \quad (\because k_{i^*} \geq k+1) \\
&= b(k+1) - \gamma_{i^*-1}(b(k+1) - (M-k-1)(N-k-1)) \\
&\leq b(k+1) \quad (\because b > (M-k-1)(N-k-1)/(k+1)).
\end{aligned}$$

This contradicts the assumption that $a_{BS}(b) > b(k+1)$. Therefore, the only other possibility is that $k_i \leq k$ for all i. In this case too, $a(N_s+1) = b\sum_{i=1}^{N_s} r_i \leq b(k+1)$ which implies that the assumption $a_{BS}(b) > b(k+1)$ is incorrect. Hence proved. ■

Note that for $(M-k-1)(N-k-1)/(k+1) \leq b \leq (M-k)(N-k)/(k+1)$ the achievable exponent in Theorem 2.1 is also $b(k+1)$. Hence, Theorem 2.1 along with Theorems 2.2 and 2.3 fully characterize the exponent achievable with any broadcast scheme.

Finite Number of Layers: In practice it is not possible to have infinitely many layers and it is important to study the performance of the broadcast scheme with a finite number of layers. The problem of finding the optimal distortion SNR exponent for a finite number of layers can be posed as the following optimization problem.

$$
\begin{aligned}
\max \quad & a \qquad (34)\\
\text{subject:} \quad & \text{for all } i \in \{1,2,\ldots,N_s\}\\
& \gamma_i \geq 0, \delta_i \geq 0, r_i \geq 0, k_i \in \{0,1,\ldots,m-1\},\\
& \gamma_{i-1} > \gamma_i, \gamma_0 = 1,\\
& \delta_i < \gamma_{i-1} - \gamma_i,\\
& r_i = k_i(\gamma_{i-1}-\gamma_i) + \delta_i,\\
& a \leq b\sum_{j=1}^{i-1} r_j + (m-k_i)(n-k_i)\gamma_{i-1} - (m+n-1-2k_i)\delta_i,\\
& a \leq b\sum_{j=1}^{N_s} r_j.
\end{aligned}
$$

For a fixed set of k_i's this reduces to a linear program. For small N_s, the optimum exponent can be found by using the linear program for all m^{N_s} choices of k_i's .

In Fig. 3 and Fig. 4, the distortion SNR exponent corresponding to the broadcast scheme proposed in Theorem 2.1 is shown for a 3×4 and a 3×6 MIMO system. The optimal distortion SNR exponent corresponding to the broadcast scheme with 10 layers is also shown. We see that the exponent with finite layers is very close to the best achievable distortion exponent of the broadcast scheme for all b and the curves overlap for a large range of b. Also as proved in Theorem 2.2 and 2.3, the distortion exponent with finite layers does not improve on the achievable exponent specified in Theorem 2.1.

B. Layering in Time with one Broadcast layer at the end

Consider the scheme shown in Fig. 5. For $b > b_k = (m-k)(n-k)/(k+1)$, $k \in \{1,\ldots,m\}$, a bandwidth of $b - b_k$ is allocated for time layering and the remaining bandwidth of b_k is allocated to a broadcast scheme where the rate and power allocation for the broadcast layers are chosen as specified in Theorem 2.1. The parameter k determines the bandwidth splitting between the broadcast layer and the time layers. The decoding proceeds by first decoding the time layers and then decoding the broadcast layers after all the time layers are decoded. This is similar to the HDA scheme of [5] and the HLS of [1] where the

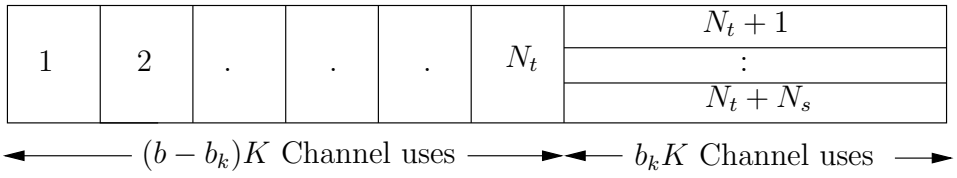

Fig. 5. Layered Schemes with Broadcast Layer at the end (LSBLEND)

source is quantized and transmitted using time layering in a bandwidth of $b - 1/m$ and the quantization error is transmitted in an analog layer of bandwidth $1/m$. For the proposed scheme, the distortion SNR exponent obtained for a particular bandwidth splitting parameter k is given in the following theorem. The largest achievable distortion SNR exponent is then obtained by taking a supremum over all k.

Note that when $k = m$, the bandwidth allocated to the broadcast layer is 0, i.e., we have only time layering. This scheme, termed Layered Scheme (LS), was proposed and analyzed in [1]. The proof of the following theorem is similar to the derivation of the exponent for LS in [1].

Theorem 2.4: Let $c_j = (m + n - 1 - 2j) \log \frac{j+1}{j}$ for $j = 0, \ldots, m$. Let p be such that $\sum_{j=p+1}^{k-1} c_j \leq (b - b_k) < \sum_{j=p}^{k-1} c_j$. Then, the best distortion SNR exponent $a(b)$ achievable using LSBLEND is given by

$$a(b) = mn - p - p^2 - (m + n - 1 - 2p)(p + 1)e^{-\frac{b-b_k-\sum_{j=p+1}^{k-1} c_j}{m+n-1-2p}}. \tag{35}$$

Proof: Let N_t and N_s denote the number of time and superposition layers respectively. Let $a(i)$ for $i = 1, \ldots, N_t$ denote the distortion SNR exponent corresponding to the case when the time layers 1 to $i - 1$ are decoded and decoding of the ith time layer fails, $a(N_t + i)$ for $i = 1, \ldots, N_s$ denote the distortion SNR exponent corresponding to the case when all N_t time layers and the first $i - 1$ broadcast layers are decoded while decoding of the ith broadcast layer fails, and let $a(N_t + N_s + 1)$ denote the exponent corresponding to the case when all layers are decoded.

For the ith time layer, the probability of decoding failure is given by $P_e(i) \doteq \rho^{-d^*(r_i)}$ where r_i is the multiplexing rate of the ith time layer and $d^*(r_i)$ is the Zheng and Tse diversity multiplexing tradeoff function specified in (4). Note that power allocation to the time layer is $\rho^1 - \rho^0$ and $d^*(r_i) = d^*(r_i, 1, 0)$. The bandwidth allocated to a time layer is $(b - b_k)/N_t$. The distortion SNR exponent of the ith time layer is then given by

$$a(i) = \frac{b - b_k}{N_t} \sum_{j=0}^{i-1} r_j + d^*(r_i) \tag{36}$$

where $r_0 = 0$.

For the broadcast layer we use the rate and power allocation as specified in Theorem 2.1. With that rate and power allocation it follows that the exponents $a(N_t + 1), a(N_t + 2), \ldots a(N_t + N_s + 1)$ are all

equal and are given by

$$\begin{aligned} a(N_t+i) &= \frac{b-b_k}{N_t}\sum_{j=0}^{N_t} r_j + (k+1)b_k \\ &= \frac{b-b_k}{N_t}\sum_{j=0}^{N_t} r_j + (m-k)(n-k) \end{aligned} \tag{37}$$

for $i=1$ to N_s+1 in the limit $N_s \to \infty$. Note that we do not loose optimality here by fixing the rate and power allocation of the broadcast layer since $(m-k)(n-k)$ is the maximum possible contribution that the broadcast layer of bandwidth b_k can make to the exponent (see Theorem 2.2 and Theorem 2.3).

In the following proof, we optimize r_i's to maximize the distortion SNR exponent.

In section B of the Appendix we show that the exponent is maximized by choosing r_i's such that $a(1)=a(2)=\ldots=a(N_t)=a(N_t+1)$ provided that the resulting r_i's lie between 0 and m. By setting $a(N_t)=a(N_t+1)$ we obtain

$$d^*(r_{N_t}) = \frac{b-b_k}{N_t} r_{N_t} + (m-k)(n-k). \tag{38}$$

We will consider the limiting case when $N_t \to \infty$. From (38) we have, in the limiting case,

$$d^*(r_{N_t}) \to (m-k)(n-k). \tag{39}$$

Therefore,

$$(m-k_{N_t})(n-k_{N_t}) - (m+n-1-2k_{N_t})\delta_{N_t} \to (m-k)(n-k). \tag{40}$$

This happens when $k_{N_t}=k-1$ and $\delta_{N_t}\to 1$.

By setting $a(i-1)=a(i)$ we have

$$d^*(r_{i-1}) = \frac{b-b_k}{N_t} r_{i-1} + d^*(r_i). \tag{41}$$

$d^*(r)$ is a decreasing function and from (41) we have $d^*(r_{i-1}) \geq d^*(r_i)$. Therefore $r_{N_t} \geq r_{N_t-1} \geq \ldots \geq r_1$. Let r_i lie between t and $t+1$. We want to check if r_{i-1} also lies between t and $t+1$. To do so we assume that $k_{i-1}=t$ and solve for δ_{i-1}. If the resulting δ_{i-1} lies between 0 and 1, then the assumption $k_i=t$ is correct. From (41) we have

$$\begin{aligned} (m-t)(n-t) - (m+n-1-2t)\delta_{i-1} &= \frac{b-b_k}{N_t}(t+\delta_{i-1}) + (m-t)(n-t) - (m+n-1-2t)\delta_i. \\ \Rightarrow \delta_{i-1}(m+n-1-2t+\frac{b-b_k}{N_t}) &= \delta_i(m+n-1-2t) - \frac{b-b_k}{N_t}t. \\ \Rightarrow \delta_{i-1} &= \alpha\delta_i - (1-\alpha)t \end{aligned} \tag{42}$$

where

$$\alpha = \frac{m+n-1-2t}{m+n-1-2t+(b-b_k)/N_t} < 1. \tag{43}$$

On using recursion (42) N_l times we have

$$\delta_{i-N_l} = \alpha^{N_l}\delta_i - \frac{1-\alpha^{N_l}}{1-\alpha}(1-\alpha)t = \alpha^{N_l}(t+\delta_i) - t. \tag{44}$$

The maximum number of times the recursion can be used such that the resulting δ is positive is given by

$$\begin{aligned}
\alpha^{N_l}(t+\delta_i) &\geq t \\
\Rightarrow N_l \log\alpha &\geq \log\frac{t}{t+\delta_i} \\
\Rightarrow \frac{N_l}{N_t} &\leq \frac{1}{N_t\log\alpha}\log\frac{t}{t+\delta_i} \qquad \because \alpha<1,\ \log\alpha<0 \\
\Rightarrow \frac{N_l}{N_t} &\leq -\frac{1}{\log\left(\left(1+\frac{b-b_k}{(m+n-1-2t)N_t}\right)^{N_t}\right)}\log\frac{t}{t+\delta_i} \\
\Rightarrow \frac{N}{N_t} &\leq \frac{m+n-1-2t}{b-b_k}\log\frac{t+\delta_i}{t} \qquad (N_t\to\infty).
\end{aligned}$$

For the proposed scheme, we start from $r_{N_t}=k$ ($k_{N_t}=k-1$ and $\delta_{N_t}=1$) and solve for r_{i-1} from r_i. Let $c_j=(m+n-1-2j)\log\frac{j+1}{j}$. If p is such that $\sum_{j=p+1}^{k-1}c_j\leq(b-b_k)<\sum_{j=p}^{k-1}c_j$ then as i decreases from N_t, after a fraction $\sum_{j=p+1}^{k-1}c_j/(b-b_k)$ of the time layers, r_i decreases from k to $p+1$. For the remaining fraction $(1-\sum_{j=p+1}^{k-1}c_j/(b-b_k))$ of layers, as i decreases, r_i decreases but remains above p, i.e., k_i remains constant at p while δ_i decreases. From (44) we can calculate r_1 as

$$\begin{aligned}
r_1 &= p+\lim_{N_t\to\infty}\alpha^{N_t(1-\frac{1}{b-b_k}\sum_{j=p+1}^{k-1}c_j)}(p+1)-p \\
&= (p+1)e^{-(\frac{b-b_k}{m+n-1-2p})(1-\frac{1}{b-b_k}\sum_{j=p+1}^{k-1}c_j)}. \qquad (45)
\end{aligned}$$

The final exponent is given by

$$\begin{aligned}
a(1)=d^*(r_1) &= (m-p)(n-p)-(m+n-1-2p)(r_1-p) \\
&= mn-p-p^2-(m+n-1-2p)r_1
\end{aligned}$$

which is the desired result. ■

Note that when $m=n$ and $k=m-1$, the contribution to the distortion SNR exponent by the broadcast layer is $b_k(k+1)=1$ and it uses a bandwidth of $b_k=1/m$. In the HLS scheme, the analog layer uses a bandwidth of $b_0=1/m$ and it also has a contribution of $mb_0=1$ towards the exponent. Therefore, in this case, the distortion SNR exponent obtained with LSBLEND with $k=m-1$ is identical to that with HLS. Therefore, the distortion SNR exponent obtained using LSBLEND becomes identical to that obtained using HLS when (a) $m=n$ and (b) the supremum occurs at $k=m-1$. It can be shown that LSBLEND is strictly better otherwise for $b>1/m$.

C. Digital Layering in Time and Using Superposition

The source is encoded in such a way that it is successively refinable. The transmitted signal composes of N_t time layers where each time layer is a superposition of N_s layers. To the (i,j)th layer, i.e., the jth time layer and the ith superposition layer within it, we allocate a power level of $\rho^{\gamma_{i-1,j}}-\rho^{\gamma_{i,j}}$ and we use a rate of transmission of $r_{i,j}\log\rho$. This corresponds to a source coding rate of $(b/N_t)r_{i,j}\log\rho$. The order in which the source coded bits are mapped to the transmission layers is important. The source coded

1	2	3							N_t
N_t+1	N_t+2								
									N_tN_s

Fig. 6. Box Scheme

bits are successively mapped on to the transmitted layers from top left to bottom right going along each row. That is, in the order $(1,1),\ldots,(1,N_t),(2,1),\ldots,(2,N_t),\ldots,(N_s,N_t)$ (see Fig. 6). The decoding proceeds in the same order and when a layer cannot be decoded, the source is reconstructed using all the layers that have been successfully decoded up to that layer.

Let $\overline{r}_{(i-1)N_t+j}\log\rho = (b/N_t)\left(\sum_{p=1}^{i-1}\sum_{q=1}^{N_t} r_{p,q} + \sum_{q=1}^{j-1} r_{i,q}\right)\log\rho$ denote the cumulative source coding rate up to the (i,j)th layer. As in the broadcast scheme case, we can approximate the overall distortion up to an exponential order by

$$D \doteq \sum_i \sum_j \rho^{-d^\star(r_{i,j},\gamma_{i-1,j},\gamma_{i,j})+\overline{r}_{(i-1)N_t+j}} + \rho^{-\overline{r}_{N_sN_t+1}}. \tag{46}$$

Let r and γ denote the set of $r_{i,j}$'s and $\gamma_{i,j}$'s. For a given r,γ, the overall exponent of the scheme $a(b,r,\gamma)$ is then,

$$a(b,r,\gamma) = \min_{i,j}(d^\star(r_{i,j},\gamma_{i-1,j},\gamma_{i,j}) + \overline{r}_{(i-1)N_t+j}, \overline{r}_{N_sN_t+1}). \tag{47}$$

The best achievable exponent with this scheme $a(b)$ is then given by

$$a(b) = \max_{r,\gamma} a(b,r,\gamma). \tag{48}$$

If we allow for change in the bandwidth allocated to each layer, then both BS and LSBLEND become special cases of this scheme and therefore the exponent obtained from the maximization should be better than those reported earlier. We will now show that for the distortion SNR exponent, even with fixed bandwidth allocation to each layer, the Box scheme can be designed to perform at least as well as BS and LSBLEND.

Claim 2.1: The Box scheme with N_s superposition layer and N_t time layers has a distortion SNR exponent that is at least as good as that of the broadcast scheme with N_s layers.

Proof: Let the optimal power allocation for the broadcast scheme by r_i, γ_i. The exponent corresponding to the ith broadcast layer is $a_{BS}(i) = b\sum_{j=1}^{i-1} r_j + d^*(r_i,\gamma_{i-1},\gamma_i)$. Now consider the Box scheme where the power allocation to the (i,j)th layer $\gamma_{i,j}$ is set to γ_i and the rate $r_{i,j}$ = r_i. Then $a_{Box}(i,j) = b\sum_{j=1}^{i-1} r_j + \frac{b}{N_t}(j-1)r_i + d^*(r_i,\gamma_{i-1},\gamma_i)$. Clearly $\frac{b}{N_t}\sum_{i,j} r_{i,j} = b\sum r_i$ and $a_{Box}(i,j) \geq a(i)$. Therefore, $\min_{i,j}(a_{Box}(i,j), \frac{b}{N_t}\sum_{i,j} r_{i,j}) \geq \min_i(a_{BS}(i), b\sum r_i)$. In this case it is actually equal but if we optimize the power allocation of the box scheme it could possibly improve on the exponent. ■

Claim 2.2: In the limit as $N_t \to \infty$, the Box scheme has a distortion SNR exponent that is at least as good as that of LSBLEND.

Proof: Consider the case when $(b-b_k)/N_t = b/N_{t,Box}$ where $N_t, N_{t,Box}$ are positive integers. Consider a power and rate allocation for the box scheme that is identical to the LSBLEND scheme for

first N_t time layers. That is, the first N_t time layers have no superposition layers and the rate is identical to that of LSBLEND. For the remaining $N_{t,Box} - N_t$ layers we allocate power and rate with the procedure used in lemma 2.1 and therefore its contribution to the exponent is identical to the contribution of the broadcast layer of LSBLEND. Therefore, this has an exponent that is identical to that of LSBLEND. Again, by optimizing the power and rate allocation of the box scheme we could possibly improve the exponent.

For the case when $\frac{b}{b-b_k}$ is irrational, the result still holds because the achievable exponent with LSBLEND and Box scheme is a continuous function of b. ■

The maximization in (48) is difficult to perform analytically and very quickly becomes difficult to perform even numerically. The procedure described in Algorithm 1 has been used to find a suboptimal set of r, γ. Remarkably, it turns out that for a range of b, this achieves performance very close to the informed transmitter upper bound $a_{IT}(b)$. Furthermore, for the considered examples, this scheme performs nearly as well as currently known schemes for all b while it is strictly better for some range of b.

Algorithm 1 Algorithm to check if an exponent d is achievable using the proposed scheme

Step 1: Initialization - Set $\gamma_{0,j} = 1 \ \forall j$ and $\overline{r}_1 = 0$.

Step 2: For $i = 1$ to N_s

Step 3: For $j = 1$ to N_t

Step 4: If $MN\gamma_{i-1,j} + \overline{r}_{(i-1)N_t+j} < d$, set $\gamma_{i,j} = \gamma_{i-1,j}$ and goto step 10.

Step 5: Find smallest $k_{i,j} \in \{0, 1, \ldots, m-1\}$ such that $0 \leq \delta_{i,j} < \gamma_{i-1,j}$ where $\delta_{i,j} = ((M - k_{i,j})(N - k_{i,j})\gamma_{i-1,j} + \overline{r}_{(i-1)N_t+j} - d)/(M + N - 1 - 2k_{i,j})$.

Step 6: If $i = N_s$ set $\gamma_{i,j} = 0$ else set $\gamma_{i,j} = \gamma_{i-1,j} - \delta_{i,j}$

Step 7: Set $r_{i,j} = k_{i,j}(\gamma_{i-1,j} - \gamma_{i,j}) + \delta_{i,j}$.

Step 8: Update $\overline{r}_{(i-1)N_t+j+1} = \overline{r}_{(i-1)N_t+j} + (b/N_t)r_{i,j}$

Step 9: If $\overline{r}_{(i-1)N_t+j+1} > d$, exponent d is achievable. return.

Step 10: End of j loop

Step 11: End of i loop

Step 12: Exponent d is not achievable using this scheme. return.

For each (i, j) if we fix $k_{i,j} \in \{0, 1, \ldots, m-1\}$ and let $r_{i,j} = k_{i,j}(\gamma_{i-1,j} - \gamma_{i,j}) + \delta_{i,j}$ where $0 \leq \delta_{i,j} < (\gamma_{i-1,j} - \gamma_{i,j})$, then, as before, the problem of finding the optimal exponent reduces to a linear program and hence by solving it for different $k_{i,j}$'s we would expect to find an exponent that is better than that obtained using Algorithm 1. However, in Step 4 of the algorithm, notice that we skip a layer if it is not possible to allocate a non zero rate. Therefore, this layer is never in outage. However, in the linear program, if we use lemma 2.1 to compute $d^*(0, \gamma_{i-1,j}, \gamma_{i-1,j})$ we get 0 which means this layer is always in outage. Therefore, to obtain the optimal exponent, we will need to allow for a layer to be skipped in addition to allowing for different values of k for that layer. The complexity thus grows as $(M+1)^{N_s N_t}$.

The achievable exponent with this scheme increases monotonically with N_S. Interestingly, the achievable exponent with this scheme may not increase monotonically with N_t.

We also considered the following variations, which provide some gain for finite number of layers. However, the gain diminishes as the number of layers increases.

1) Adding an Analog Layer: In this scheme, we start allocating rate and power levels to the layers as in Algorithm 1. Let us denote by $\mathcal{A}_{i,j} = \{(p,q) : p \leq i-1 \text{ AND } q \leq N_t\} \cup \{(i,q) : q < j\}$ the set of all layers for which a rate and power allocation has been found during the (i,j)th stage of the algorithm. Let $\mathbf{X}^a_{i,j}$ denote the analog quantization error in quantizing the source using $\overline{r}_{(i-1)N_t+j} \log \rho$ bits. We check if at least $\lceil \frac{N_t}{bm} \rceil$ layers are still available in $\mathcal{A}^c_{i,j}$ to transmit the analog quantization error such that the desired exponent can be achieved. If this is possible, we stop there and this becomes the overall transmission scheme. Otherwise, we allocate a power level $\gamma_{i,j}$ and rate $r_{i,j}$ corresponding to the (i,j)th layer as before and continue to the next layer. Note that this contains the HLS schemes of [1, 5] as a special case (when $N_s = 1$).

2) Ordering the layers based on available power: In this variation, we allocate rate and power as in Algorithm 1 but the order of selecting the layers is not sequential. At any stage of the algorithm, we select the time layer with the maximum available power (total power minus power already allocated to superposition layers in that time layer). A new superposition layer is added to this layer with power and rate allocation as specified in Algorithm 1. Note that this is the order in which the successive refinement information from the source coder is filled and therefore the decoder should decode the layers in this order.

III. Extensions to Multiple Block Fading Channels

In this section we extend the results derived for the MIMO channel to the L-block fading MIMO channel. We assume that K source samples are transmitted over L blocks of length T/L each. The fading coefficient for the different blocks are independent.

Lemma 3.1: If the multiplexing gain in the ith layer of the broadcast scheme is $r_i = \frac{kL+a}{L}(\gamma_{i-1} - \gamma_i) + \delta$ where $k \in \{0, 1, \ldots, m-1\}$, $a \in \{0, 1, \ldots, L-1\}$ and $0 \leq \delta < \frac{\gamma_{i-1}-\gamma_i}{L}$, then, the achievable diversity in the ith layer of the broadcast scheme, assuming that the message transmitted in the previous layers is available at the receiver, is given by

$$d^\star(r_i, \gamma_{i-1}, \gamma_i) = L(m-k)(n-k)\gamma_{i-1} - (m+n-1-2k)(a\gamma_{i-1} + L\delta).$$

That is, if $X = \frac{1}{\sqrt{\rho}}(\sum_{i=1}^{N_s} \sqrt{\rho^{\gamma_{i-1}} - \rho^{\gamma_i}} X_i + \sqrt{\rho^{\gamma_{N_s}}} N_1)$, where $X_i, N_1 \sim \mathcal{N}(0, I^{M \times M})$, $Y_l = \sqrt{\frac{\rho}{M}} \mathbf{H_l} X + N$ for $l = 1, \ldots, L$, and $\mathcal{A}_i = \{H_1, \ldots, H_L : \frac{1}{L}\sum_{l=1}^{L} I(X_i; Y_l | \mathbf{H_1} = H_1, \ldots, \mathbf{H_L} = H_L, X_1, \ldots X_{i-1}) < r_i \log \rho)$ denotes the outage event set then $P(\mathcal{A}_i) \doteq \rho^{-d^\star(r_i, \gamma_{i-1}, \gamma_i)}$.

Proof:

$$P(\mathcal{A}_i) = P\left(\frac{1}{L} \sum_{l=1}^{L} \log \frac{\det(I + \frac{1}{M}\rho^{\gamma_{i-1}} \mathbf{H_l} \mathbf{H_l}^H)}{\det(I + \frac{1}{M}\rho^{\gamma_i} \mathbf{H_l} \mathbf{H_l}^H)} < r_i \log \rho \right). \tag{49}$$

Let $\lambda_{1,l}, \ldots, \lambda_{m,l}$ denote the non-zero ordered eigenvalues of $\mathbf{H_l}\mathbf{H_l}^H)$ with $\lambda_{1,l} \leq \lambda_{2,l} \leq \ldots \lambda_{m,l}$. As in [4], let $\alpha_{j,l} = -\frac{\log \lambda_{j,l}}{\log \rho}$. Therefore, $\alpha_{1,l} \geq \alpha_{2,l} \geq \ldots \alpha_{m,l}$. At high SNR, $P(\mathcal{A}_i) \doteq P(\mathcal{A}')$ where

$$\mathcal{A}' = \left\{ \alpha : \frac{1}{L} \sum_{l=1}^{L} \sum_{j=1}^{m} \left((\gamma_{i-1} - \alpha_{j,l})^+ - (\gamma_i - \alpha_{j,l})^+ \right) < r_i \right\}. \tag{50}$$

Following in the footsteps of [4], we observe that the outage probability is given by $P(\mathcal{A}_i) \doteq \rho^{-d^\star(r_i,\gamma_{i-1},\gamma_i)}$ where

$$d^\star(r_i,\gamma_{i-1},\gamma_i) = \inf_{\mathcal{A}'\cap\boldsymbol{\alpha}^+} \sum_{j=1}^{m}\sum_{l=1}^{L}(2j-1+n-m)\alpha_{j,l}. \tag{51}$$

For $r_i = \frac{kL+a}{L}(\gamma_{i-1}-\gamma_i)+\delta$ where $k \in [0,1,\ldots,m-1]$, $a \in [0,1,\ldots,L-1]$, and $0 \le \delta < \frac{\gamma_{i-1}-\gamma_i}{L}$, the infimum in (51) occurs when $\alpha = \alpha^*$ where

$$\alpha^*_{j,l} = \begin{cases} \gamma_{i-1}, & 1 \le j < m-k; \\ \gamma_{i-1}, & j = m-k, 1 \le l < L-a; \\ \gamma_{i-1}-L\delta, & j = m-k, l = L-a; \\ 0, & j = m-k, L-a < l \le L; \\ 0, & m-k < j \le m \end{cases} \tag{52}$$

Hence,

$$\begin{aligned} & d^\star(r_i,\gamma_{i-1},\gamma_i) \\ &= \sum_{j=1}^{m-k-1}(2j-1+n-m)L\gamma_{i-1} + (2(m-k)-1+n-m)((L-a)\gamma_{i-1}-\delta) \\ &= \sum_{j=1}^{m-k}(2j-1+n-m)L\gamma_{i-1} - (2(m-k)-1+n-m)(a\gamma_{i-1}+L\delta) \\ &= L(m-k)(2\frac{m-k+1}{2}-1+n-m)\gamma_{i-1} - (m+n-1-2k)(a\gamma_{i-1}+L\delta). \end{aligned}$$

This then gives the desired result. ■

Theorem 3.1: The broadcast scheme achieves a distortion SNR exponent of $\frac{kL+a+1}{L}b$, $k \in \{0,1,\ldots,m-1\}$, $a \in \{0,1,\ldots,L-1\}$ for $\frac{L(M-k)(N-k)-(a+1)(M+N-1-2k)}{kL+a+1} < \frac{b}{L} < \frac{L(M-k)(N-k)-a(M+N-1-2k)}{kL+a+1}$ with power and rate allocation

$$\gamma_i = \alpha^i \tag{53}$$

and

$$r_i = \frac{kL+a+1}{L}(\gamma_{i-1}-\gamma_i) - \epsilon \tag{54}$$

where

$$\alpha = 1 + a + \frac{b\frac{kL+a+1}{L} - L(M-k)(N-k)}{M+N-1-2k} \tag{55}$$

for arbitrarily small $\epsilon > 0$.

Proof: The power and rate allocation policy can be derived in a manner similar to that in Theorem 2.1. Here we will just verify that the specified rate and power allocation policy indeed gives the specified exponent.

We first note that for $\frac{L(M-k)(N-k)-(a+1)(M+N-1-2k)}{kL+a+1} < \frac{b}{L} < \frac{L(M-k)(N-k)-a(M+N-1-2k)}{kL+a+1}$, $0 < \alpha < 1$ and therefore the specified rate and power allocation is a valid assignment.

As in Theorem 2.1 the distortion SNR exponent is given by

$$a_{BS} = \min(b\sum_j r_j, a(1), \ldots, a(i), \ldots) \tag{56}$$

where

$$a(i) = b\sum_{j=1}^{i-1} r_j + d^*(r_i, \gamma_{i-1}, \gamma_i). \tag{57}$$

We have

$$\lim_{i\to\infty} b\sum_{j=1}^{i} r_j = b\frac{kL+a+1}{L}(1-\lim_{i\to\infty}\gamma_i) = b\frac{kL+a+1}{L}. \tag{58}$$

Furthermore, from (57) and lemma 3.1 we have

$$\begin{aligned} a(i) &= b\frac{kL+a+1}{L}(1-\gamma_{i-1}) + L(m-k)(n-k)\gamma_{i-1} - (m+n-1-2k)((a+1)\gamma_{i-1}-\gamma_i) \\ &= b\frac{kL+a+1}{L} + (m+n-1-2k)\gamma_i \\ &\quad +\gamma_{i-1}\left(L(m-k)(n-k) - (m+n-1-2k)(a+1) - b\frac{kL+a+1}{L}\right) \\ &= b\frac{kL+a+1}{L} + (m+n-1-2k)(\gamma_i - \alpha\gamma_{i-1}) = b\frac{kL+a+1}{L}. \end{aligned}$$

Therefore, $a_{BS} = b\frac{kL+a+1}{L}$. ■

By comparing with the upper bound, we observe that the broadcast scheme achieves the optimal exponent of mb for $b < \frac{n-m+1}{m}$ and MNL for $b > MNL^2$. This has been shown earlier for the $M = N = 1$ case in [2] and for the $L = 1$ case in [1].

Theorem 3.2: Let $c_{kL+a} = L(m+n-1-2k)\log\left(\frac{kL+a+1}{kL+a}\right)$ for $k \in \{0, 1, \ldots, m-1\}$ and $a \in \{0, 1, \ldots, L-1\}$. Consider the time layering scheme with a broadcast layer of bandwidth $b_{kL+a} = \frac{(m-k)(n-k)L^2 - aL(n+m-1-2k)}{kL+a+1}$ at the end. Let k_1 and a_1 be such that $\sum_{j=k_1L+a_1+1}^{kL+a-1} c_j < b - b_{kL+a} < \sum_{j=k_1L+a_1}^{kL+a-1} c_j$ where $k_1 \in \{0, 1, \ldots, m-1\}$ and $a_1 \in \{0, 1, \ldots, L-1\}$. The distortion SNR exponent is then given by

$$a_{kL+a}(b) = (m-k_1)(n-k_1)L - (r_1-k_1)L(n+m-1-2k_1) \tag{59}$$

where

$$r_1 = (k_1 + \frac{a_1+1}{L})e^{-\frac{b-b_{kL+a}-\sum_{i=k_1L+a_1+1}^{kL+a-1} c_i}{L(m+n-1-2k_1)}}. \tag{60}$$

Proof: The proof is similar to that of Theorem 2.4 and is skipped here. ■

IV. Numerical Results

The achievable exponent using the proposed hybrid layering scheme along with that achievable by the HLS and broadcast schemes of [1] are shown in Fig. 7 and Fig. 8. Note that the proposed schemes outperforms the schemes in [1] for all b, making this the best known achievable distortion SNR exponent.

The optimal exponent can be obtained for all $b < (n-m+1)/m$ using the purely digital scheme in Section II-A. This is the first time a scheme has been shown to obtain the optimal exponent for $1/m < b < (n-m+1)/m$. Since the scheme in Section II-A is a special case of the scheme in Section II-C, the optimal exponent is achieved in this region by the scheme in Section II-C as well.

A plot of the distortion SNR exponent for $M = N = L = 2$ is shown in Fig. 10.

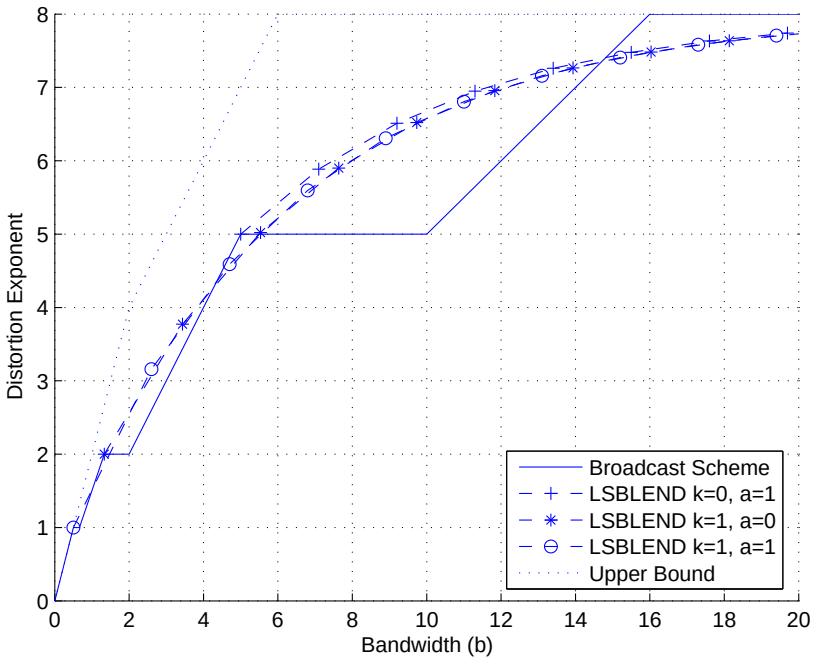

Fig. 7. Achievable distortion SNR exponent for $M = N = 2$

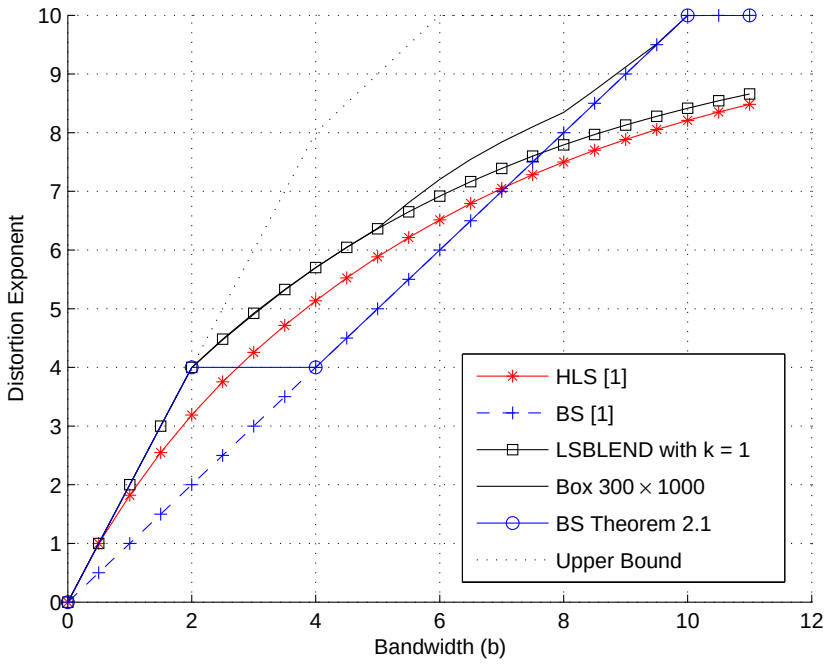

Fig. 8. Achievable distortion SNR exponent for $M = 2, N = 5$

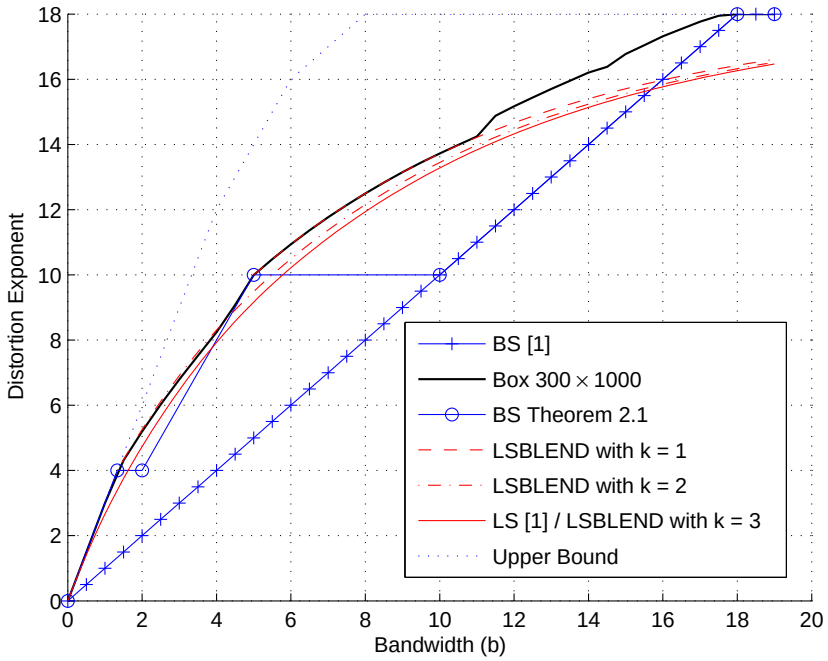

Fig. 9. Achievable distortion SNR exponent for $M = 3, N = 6$

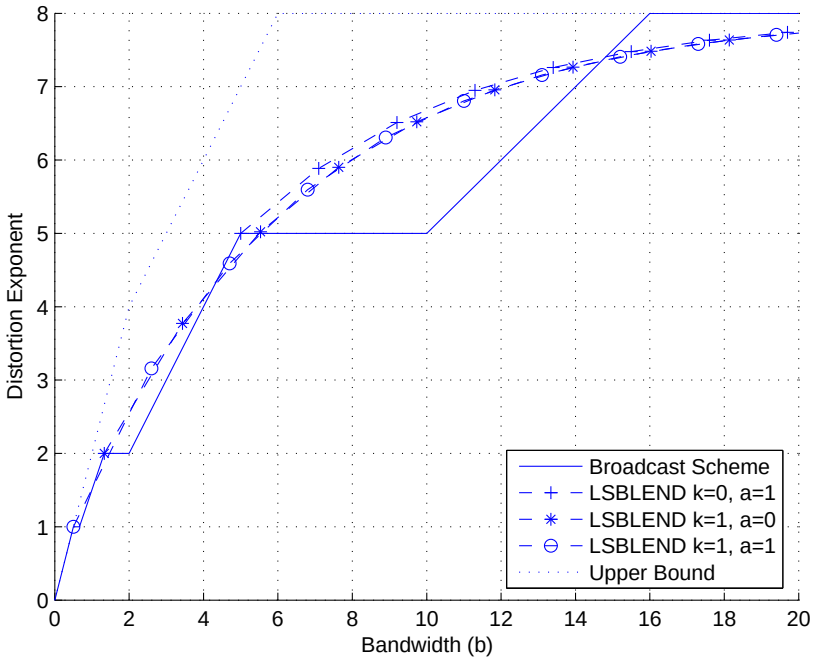

Fig. 10. Achievable distortion SNR exponent for $M = N = L = 2$

V. Conclusion

We have proposed layering schemes for transmitting a discrete time analog source over a block fading MIMO channel. Achievable distortion SNR exponent using carefully selected rate and power allocation policies for these scheme have been studied. The achievable distortion SNR exponent obtained using these schemes is better than those reported in [1, 5] making this the best known distortion SNR exponent so far. Particularly, the optimal exponent is obtained for $b < (n-m+1)/m$ and $b > mnL^2$. We believe this is a new and surprising result. Our current research focusses on optimizing the rate and power allocation of these schemes.

Appendix

A. Optimality of equating exponents for the BS

The exponent $a(b)$ is given by the following optimization problem

$$\begin{aligned} a(b) \quad &= - \min_{a,\gamma_1,\ldots,\gamma_{N_s}} -a \\ &\text{subject to:} \\ &C_i = a - b(k+1)(1-\gamma_{i-1}) - (m-k)(n-k)\gamma_{i-1} + (m+n-1-2k)(\gamma_{i-1}-\gamma_i) \leq 0 \\ &\qquad \text{for } i = 1, 2, \ldots, N_s; \\ &C_{N_s+1} = a - b(k+1)(1-\gamma_{N_s}) \leq 0; \\ &\gamma_{i+1} \leq \gamma_i; \quad \gamma_{N_s} \geq 0; \quad \gamma_0 = 1. \end{aligned}$$

We solve this optimization problem by ignoring the constraints $\gamma_{i+1} \leq \gamma_i$ and $\gamma_{N_s} \geq 0$. Any solution then is an upper bound on $a(b)$. Furthermore, if the solution satisfies the ignored constraints then the solution yields $a(b)$. Consider the function $F = -a + \sum_{i=1}^{N_s+1} \lambda_i C_i$. Setting $dF/d\gamma_i = 0$ we have for $i = 1$ to $N_s - 1$

$$\begin{aligned} \frac{dF}{d\gamma_i} &= -\lambda_i(m+n-1-2k) + \lambda_{i+1}(b(k+1) - (m-k)(n-k) + (m+n-1-2k)) = 0 \\ &\Rightarrow \lambda_i = \frac{b(k+1) - (m-k)(n-k) + (m+n-1-2k)}{m+n-1-2k}\lambda_{i+1} = \alpha\lambda_{i+1}. \end{aligned}$$

For $i = N_s$

$$\frac{dF}{d\gamma_{N_s}} = -\lambda_{N_s}(m+n-1-2k) + \lambda_{N_s+1}b(k+1) = 0. \tag{61}$$

Therefore, we have

$$\lambda_i = \alpha^{N_s-i}\frac{b(k+1)}{m+n-1-2k}\lambda_{N_s+1}. \tag{62}$$

Setting $dF/da = 0$ we have

$$-1 + \sum \lambda_i = 0. \tag{63}$$

We are interested in the region $b > (m-k-1)(n-k-1)/(k+1)$ and therefore $\alpha > 0$. So all λ's are strictly positive. Therefore, from the KKT conditions, it follows that the optimal solution satisfies $C_i = 0$ for $i = 1$ to $N_S + 1$.

B. Optimality of equating exponents for LSBLEND

The exponent $a(b)$ is given by the following optimization problem

$$\begin{aligned} a(b) \quad &= - \min_{a,r_1,\ldots,r_{N_t}} -a \\ &\text{subject to:} \\ &C_i = a - \frac{b-b_k}{N_t}\sum_{j=0}^{i-1} r_j - d^*(r_i) \le 0 \qquad \text{for } i = 1,2,\ldots,N_t; \\ &C_{N_t+1} = a - \frac{b-b_k}{N_t}\sum_{j=0}^{N_t} r_j + b_k(k+1) \le 0; \\ &r_i \ge 0; \quad r_i < m; \quad r_0 = 0. \end{aligned}$$

As in Appendix A we ignore the constraints $0 < r_i < m$ and consider the function $F = -a + \sum_{i=1}^{N_t+1} \lambda_i C_i$. Setting $dF/dr_i = 0$ we have for $i = 1$ to N_t

$$\frac{dF}{dr_i} = -\frac{b-b_k}{N_t}\sum_{j=i+1}^{N_t+1} \lambda_j - \lambda_i \frac{d}{dr_i}(d^*(r_i)) = 0. \tag{64}$$

Note that $\frac{b-b_k}{N_t} > 0$ and $\frac{d}{dr_i}(d^*(r_i)) < 0$. Starting from $i = N_t$ and solving recursively for λ_i in terms of λ_{N_t+1} we observe that the λ_i's are of form $\alpha_i \lambda_{N_s+1}$ where $\alpha_i > 0$. By setting $dF/da = 0$ we have $\sum_{i=1}^{N_t+1} \lambda_i = 1$. Therefore, $\lambda_i > 0$ for all i and hence, from the KKT conditions, we conclude that the optimal solution satisfies $C_i = 0$ for $i = 1$ to $N_t + 1$.
